Ubiquitous tyrosinase catalyses the aerobic oxidation of phenols to catechols through the binuclear copper centres. Here, inspired by the Fischer indole synthesis, we report an iridium-catalysed tyrosinase-like approach to catechols, employing an oxyacetamide-directed C–H hydroxylation on phenols. This method achieves one-step, redox-neutral synthesis of catechols with diverse substituent groups under mild conditions. Mechanistic studies confirm that the directing group (DG) oxyacetamide acts as the oxygen source. This strategy has been applied to the synthesis of different important catechols with fluorescent property and bioactivity from the corresponding phenols. Finally, our method also provides a convenient route to $^{18}$O-labelled catechols using $^{18}$O-labelled acetic acid.
Catechols are essential bioactive molecules in human metabolism and normal physiological activities, acting as effective structural units in many bronchodilator, adrenergic, anti-parkinsonian and anti-hypertensive drugs (Fig. 1a)\(^1\). For example, L-dopa is a well-known drug used for the treatment of Parkinson’s disease and is converted from L-tyrosine via catalysis by tyrosine hydroxylase in the central nervous system under mild conditions. The dopamine system plays a central role in several significant medical conditions, including attention deficit hyperactivity disorder (ADHD), schizophrenia and addictions\(^2\). On the other hand, estradiol is important in the regulation of the female oestrous and menstrual reproductive cycles\(^3\).

Synthesis of catechols usually requires lengthy steps and harsh reaction conditions, with low selectivity and conversion rates\(^4\). To develop efficient routes to synthesize catechols, we aim to construct a new C–O bond at the ortho position of phenols through directed C–H bond oxygenation. The catalytic transformation of the C–O bond from benzene to phenol is considered to be one of the greatest challenges in catalytic chemistry\(^5\). Tremendous progress has been achieved in directed C–H hydroxylation/oxygenation by metal catalysis with O\(_2\) (refs 6–9), H\(_2\)O (refs 10–12), peroxides\(^13–18\) or the in situ hydrolysis of newly installed acyloxy groups as oxygen sources such as OAc, OTFA and so on (refs 19–30) (Fig. 1b). Notably, Yu and colleagues\(^6\) first developed a versatile Pd-catalysed ortho-hydroxylation of benzoic acids at 1 atm of O\(_2\) or air under non-acidic conditions. Gevorgyan and colleagues\(^31\) recently reported an ingenious silanol-directed Pd-catalysed C–H oxygenation of phenols followed by desilylation of the silacycle with tetrabutylammonium fluoride (TBAF), furnishing catechols with PhI(OAc)\(_2\) as the oxygen source. Rao and colleagues\(^32\) demonstrated the efficient ruthenium(II)- and palladium(II)-catalysed C–H hydroxylation of aryl carbamates and a subsequent deprotection to afford catechols in good yields. These pioneering works used TFA/TFAA as the oxygen source\(^26\).

We have recently reported a number of metal-catalysed C–H bond functionalizations based on a powerful directing group, -O–NHAc (oxyacetamide), which can act as an internal oxidant to yield versatile phenol derivatives\(^33,34\). A variety of substituted substrates with -O–NHAc directing group were easily prepared from phenols or aryl boronic acid compounds\(^35–38\). Inspired by the classic Fischer indole synthesis\(^39–41\), we hypothesized that catechols would be furnished from N-phenoxyacetamides provided that the acetamide group could function as an intramolecular oxygen source. By choosing appropriate metal catalysts, the acetamide group could function as a directing group, an internal oxidant and an oxygen source simultaneously (Fig. 1c)\(^38,42–45\). This design would avoid the need for an external oxidant, which could be detrimental to the fragile polyphenols. Notably, seminar reports from the Cheung and Buchwald\(^46\), and Zhao and colleagues\(^47\) clearly established that the acetamide group could participate in C–O bond formation.

Herein, we report an iridium-catalysed, one-step, mild and redox-neutral synthesis of catechols from acetamide-protected phenols, employing a bioinspired intramolecular oxygen transfer strategy.

**Results**

**Model studies**. We first explored Zn-, Al-, Fe-, Cu-, Pd- and Ru-catalysed systems to N-phenoxyacetamides (1a). Unfortunately, the target product (2a) was not detected. The same result was shown in the common Rh-catalysed system for -O–NHAc (Table 1, entries 1–10 and Supplementary Table 1). Considering...
the design of the internal oxidation pathway, we made further attempts using other metal catalysts in the absence of an external oxidant. Gratifyingly, using 5 mol% [Cp*IrCl2]2 as catalyst and 2 equiv. of di-tert-butyl peroxide (DTBP) as a possible oxygen source and heating in MeOH at 70 °C for 12 h, the target product catechol 2a was obtained in 25% yield (Table 1, entry 12). Concurrently, a mixture of phenol byproducts from the self-decomposition of N-phenoyacetamides was detected. According to the literature and our past experience, the reaction temperature and acid–alkali environment are important factors in the self-decomposition of N-phenoyacetamides. It was surprising to find that target product was synthesized in the absence of DTBP when one equivalent of AcOH was added (Table 1, entry 13). Lowering the temperature greatly improved the yield. At room temperature, the reaction proceeded to give 67% yield (Table 1, entry 14). Next, the aliphatic chain (on the aromatic ring rather than the design of the internal oxidation pathway, we made further attempts using other metal catalysts in the absence of an external oxidant. Gratifyingly, using 5 mol% [Cp*IrCl2]2 as catalyst and 2 equiv. of di-tert-butyl peroxide (DTBP) as a possible oxygen source and heating in MeOH at 70 °C for 12 h, the target product catechol 2a was obtained in 25% yield (Table 1, entry 12). Concurrently, a mixture of phenol byproducts from the self-decomposition of N-phenoyacetamides was detected. According to the literature and our past experience, the reaction temperature and acid–alkali environment are important factors in the self-decomposition of N-phenoyacetamides. It was surprising to find that target product was synthesized in the absence of DTBP when one equivalent of AcOH was added (Table 1, entry 13). Lowering the temperature greatly improved the yield. At room temperature, the reaction proceeded to give 67% yield (Table 1, entry 14). Next, various acids and alkalis were tested to improve the yield. As a whole, acids were conducive to this reaction, whereas alkalis were not. Malonic acid was preferred, with a 95% gas chromatography (GC) yield and a 92% isolated yield (Table 1, entry 19). Bro-moaetic acid was slightly inferior (Table 1, entry 20), whereas HCOOH, TFA and TFA/TFAA failed to afford the product (Table 1, entries 18, 21–22). When alkali was added, no product was observed (Table 1, entry 11). In the absence of [Cp*IrCl2]2, no product was detected (Table 1, entry 23). In addition, there was no distinction under N2, O2 and air as the reaction environment. Ultimately, optimal reaction conditions to carry the ortho-hydroxylation are: 5 mol% [Cp*IrCl2]2 and 2.5 equiv. of CH2(COOH)2 in MeOH at room temperature in air with no external oxidant.

**Scope of Ir-catalysed ortho-hydroxylation.** The scope of the one-step neutral ortho-hydroxylation from N-phenoyacetamides 1 to obtain catechols 2 was investigated (Table 2). Significantly, electron-neutral and electron-rich substituents such as Me, Et, tBu and OMe groups (2a–2e, 2o and 2p), all afforded excellent selectivity and good yields. The hydroxylation of substrates with electron-withdrawing substituents such as COOH, COOMe and halogen (F, Cl, Br and I with good yield) were also well tolerated (2f–2n). Ortho-, meta- and para-substituents on N-phenoyacetamides provided similarly good yields. Remarkably, meta- and para-substituents on N-phenoyacetamides shared the same products. This finding showed a good selectivity of hydroxylation in the ortho position, which was far away from the meta-substituents (2c and 2d, 2j and 2k). In particular, the ortho-ethyl substituent substrate showed C–H activation on the aromatic ring rather than the aliphatic chain (2e).

**The synthesis of fluorescent and bioactive catechols.** Our method provided the possibility of one-step synthesis of complicated catechols (Table 3). Recently, we reported a new method to afford different fluorescent heteroarylated phenols by N-phenoyacetamides34. When ortho-heteroarylated N-phenoyacetamide 1u was subject to the standard ortho-hydroxylation conditions, the desired product 2-(2,3-
Dihydroxyphenyl)benzothiazole derivative 2u with green fluorescence was obtained in 76% yield. Our method could be a general strategy to prepare fluorescent dihydroxyl heterocycle scaffold. Next, we prepared the ONHAc-containing coumarins, the 7,8-dihydroxyl products 2v and 2w, with complete chemoselectivity in 87% and 81% yield, respectively. The product 7,8-dithydroxycoumarin 2v was commonly called Daphnetin and is an important natural product from Zushima with good anti-inflammatory and anti-oxidant activities. Our reaction could provide a powerful tool in the chemical synthesis of Daphnetin derivatives. Finally, bioactive catechols natural products such as L-dopa and estradiol were tested under the standard reaction conditions, the protected L-dopa 2x, protected dopamine 2y and estradiol 2z were successfully obtained directly with high selectivity and excellent yields, highlighting the method’s mild conditions, excellent functional group tolerance and selectivity.

**Discussion**

To understand the reaction mechanism, we first attempted to identify the oxygen source of the catechol products. With the
standard condition, using $^{18}$O-MeOH as the solvent (Fig. 2a, eq. 1), the product detected by high resolution mass spectroscopy (HRMS) did not show the $^{18}$O-labelled catechol, which meant the oxygen of the product did not come from the solvent. After that, 50 μl $^{18}$O-H$_2$O was added under the standard conditions (Fig. 2a, eq. 2). The results showed that the addition of water had no effect on the yield of catechol, but still no $^{18}$O-labelled product could be detected. It seemed as though that the oxygen of catechol did not come from the water that might be generated in the reaction.

When $^{18}$O-labelled acetic acid (CH$_3$C$^{18}$O$_{18}$OH) was added instead of malonic acid (Fig. 2a, eq. 3), the $^{18}$O-labelled product was still not detected, which showed that the acid was also not the

oxygen source of the reaction. Based on the aforementioned results, we inferred that the oxygen of the product could only come from the carbonyl of the O–NHAc group. Finally, we synthesized the substrate PhONHAc with the carbonyl labelled with 18O. Under the standard conditions, we obtained the catechol with one 18O-labelled hydroxyl (Fig. 2a, eq. 4). The 18O-labelled substrate and product were confirmed by HRMS (Fig. 3), suggesting that the reaction was an intramolecular process and that the carbonyl of the O–NHAc group was the oxygen source. This method may be a powerful tool to access a variety of 18O-labelled catechols, which could then be used to investigate the metabolic pathways of catechol-derived bioactive compounds.

To probe the active intermediate in the reaction, we treated the substrate 1a with 1 equiv. [Cp*IrCl2]2 and 2.5 equiv. Ag2CO3 (Fig. 2b), implying that species B, whereas CH3COOH or CH2(COOH)2 dissociated one molecule CH3COOH and CH2(COOH)2, respectively, by collision-induced dissociation. This result might explain why HCOOH was ineffective in promoting the reaction.

Interestingly, in the Ir/HCOOH/MeOH system, HCOOH was not an active intermediate of the reaction. Furthermore, the free energy of species A underwent a significant reduction from 22.4 to 2.1 kcal mol−1, highlighting the crucial role of acids in stabilizing species A and protonation (Supplementary Fig. 1).

Mass spectrometric experiments were carried out to explore the interaction between [Cp*IrCl2]2 and different acids (HCOOH, CH3COOH and CH2(COOH)2) (Supplementary Fig. 2). Interestingly, in the Ir/HCOOH/MeOH system, HCOOH was detected losing a molecule CO2 fragment when interacted with [Cp*IrCl2]2, whereas CH3COOH or CH2(COOH)2 dissociated one molecule CH3COOH and CH2(COOH)2, respectively, by collision-induced dissociation. This result might explain why HCOOH was ineffective in promoting the reaction.

In summary, we have described the first examples of an iridium-catalysed synthesis of catechols from phenols through a bio-inspired route allowing efficient, selective synthesis of catechols, which are useful building blocks for amino acids and pharmaceuticals. Our method also provides a convenient
route to $^{18}$O-labelled catechols using $^{18}$O-labelled acetic acid. Further applications of the Ir/malonic acid/MeOH system and mechanistic studies of the reaction are under investigation and will be reported in due course.

**Methods**

**Materials**. For NMR spectra of compounds in this study, see Supplementary Figs 1–27. For the crystallographic data of compound 3, see Supplementary Tables 1–2 and Supplementary Fig. 28. For the representative experimental procedures and analytic data of compounds synthesized, see Supplementary Methods.

**General procedure (2a)**. N-phenoxyacetamide (1) (0.2 mmol), [Cp*IrCl$_2$]$_2$ (3 mol%) and CH$_3$(COOH)$_2$ (5.0 mmol) without external oxidant were weighed into a 10 ml pressure tube, to which was added anhydrous MeOH (1 ml) in a glove box. The reaction vessel was stirred at room temperature for 10 h in air. The mixture was then concentrated under vacuum and the residue was purified by...
column chromatography on silica gel with a gradient eluent of petroleum ether and ethyl acetate to afford the corresponding product.
